## **Python Data Structures Cheat Sheet**

## List

Package/Method	Description	Code Example
append()	The 'append()' method is used to add an element to the end of a list.	<pre>Syntax:     list_name.append(element)  Example:     fruits = ["apple", "banana", "orange"]     fruits.append("mango") print(fruits)</pre>
copy()	The 'copy()' method is used to create a shallow copy of a list.	<pre>Example 1:     my_list = [1, 2, 3, 4, 5]     new_list = my_list.copy() print(new_list)     # Output: [1, 2, 3, 4, 5]</pre>
count()	The 'count()' method is used to count the number of occurrences of a specific element in a list in Python.	Example:  my_list = [1, 2, 2, 3, 4, 2, 5, 2]     count = my_list.count(2) print(count)  # Output: 4
Creating a list	A list is a built-in data type that represents an ordered and mutable collection of elements. Lists are enclosed in square brackets [] and elements are separated by commas.	<pre>Example:     fruits = ["apple", "banana", "orange", "mango"]</pre>
del	The 'del' statement is used to remove an element from list. 'del' statement removes the element at the specified index.	Example:  my_list = [10, 20, 30, 40, 50]  del my_list[2] # Removes the element at index 2 print(my_list)  # Output: [10, 20, 40, 50]

about:blank 1/6

extend()	The 'extend()' method is used to add multiple elements to a list. It takes an iterable (such as another list, tuple, or string) and appends each element of the iterable to the original list.	<pre>Example:     fruits = ["apple", "banana", "orange"]     more_fruits = ["mango", "grape"]     fruits.extend(more_fruits)     print(fruits)</pre>
Indexing	Indexing in a list allows you to access individual elements by their position. In Python, indexing starts from 0 for the first element and goes up to `length_of_list - 1`.	<pre>Example:     my_list = [10, 20, 30, 40, 50]     print(my_list[0])     # Output: 10 (accessing the first element)     print(my_list[-1])     # Output: 50 (accessing the last element using negative indexing)</pre>
insert()	The 'insert()' method is used to insert an element.	<pre>Syntax:     list_name.insert(index, element)  Example:     my_list = [1, 2, 3, 4, 5]     my_list.insert(2, 6)     print(my_list)</pre>
Modifying a list	You can use indexing to modify or assign new values to specific elements in the list.	Example:  my_list = [10, 20, 30, 40, 50]  my_list[1] = 25 # Modifying the second element  print(my_list)  # Output: [10, 25, 30, 40, 50]

```
Example 1:
                                                                                                        \label{eq:my_list} \begin{split} &\text{my_list} = \text{[10, 20, 30, 40, 50]} \\ &\text{removed\_element} = &\text{my_list.pop(2)} \text{ \# Removes and returns the element at index 2} \end{split}
                                                                                                       print(removed_element)
# Output: 30
                                                                                                        print(my_list)
# Output: [10, 20, 40, 50]
                           'pop()' method is another way to remove an
                          element from a list in Python. It removes and
                          returns the element at the specified index. If you
pop()
                          don't provide an index to the 'pop()' method, it will
                                                                                                Example 2:
                          remove and return the last element of the list by
                                                                                                        \label{eq:my_list} \begin{split} &\text{my\_list} = \text{[10, 20, 30, 40, 50]} \\ &\text{removed\_element} = &\text{my\_list.pop()} \text{ \# Removes and returns the last element} \end{split}
                                                                                                        print(removed_element)
                                                                                                        # Output: 50
                                                                                                        print(my_list)
                                                                                                        # Output: [10, 20, 30, 40]
                                                                                                Example:
                                                                                                        my_list = [10, 20, 30, 40, 50]
my_list.remove(30) # Removes the element 30
                                                                                                        print(my_list)
# Output: [10, 20, 40, 50]
                          To remove an element from a list. The 'remove()'
remove()
                          method removes the first occurrence of the
                          specified value.
                                                                                                Example 1:
                                                                                                        my_list = [1, 2, 3, 4, 5]
my_list.reverse() print(my_list)
                                                                                                        # Output: [5, 4, 3, 2, 1]
                          The 'reverse()' method is used to reverse the order
reverse()
                          of elements in a list
                          You can use slicing to access a range of elements
                                                                                                Syntax:
Slicing
                          from a list.
                                                                                                        list_name[start:end:step]
                                                                                                Example:
                                                                                                       my_list = [1, 2, 3, 4, 5]
print(my_list[1:4])
# Output: [2, 3, 4] (elements from index 1 to 3)
print(my_list[:3])
                                                                                                        # Output: [1, 2, 3] (elements from the beginning up to index 2)
```

```
sort()

The 'sort()' method is used to sort the elements of a list in ascending order. If you want to sort the list in descending order, you can pass the 'reverse=True' argument to the 'sort()' method.

The 'sort()' method is used to sort the elements of a list in ascending order. If you want to sort the list in descending order, you can pass the 'reverse=True' argument to the 'sort()' method.

Example 1:

***wy.list = [5, 2, 8, 1, 9]

**wy.list = [5, 2, 8, 1, 9]

***wy.list = [5, 2, 8, 1, 9]

**wy.list = [5, 2, 8, 1,
```

Tunle

Package/Method	Description	Code Example
		Syntax: tuple.count(value)
count()	The count() method for a tuple is used to count how many times a specified element appears in the tuple.	<pre>Example:     fruits = ("apple", "banana", "apple", "orange")     print(fruits.count("apple")) #Counts the number of times apple is found in tuple. #Output: 2</pre>
index()	The index() method in a tuple is used to find the first occurrence of a specified value and returns its position (index). If the value is not found, it raises a ValueError.	Syntax: tuple.index(value)

```
Example:
                                                                                              fruits = ("apple", "banana", "orange")
print(fruits[1]) #Returns the value at which apple is present.
#Output: banana
                                                                                       Syntax:
                                                                                              sum(tuple)
                         The sum() function in Python can be used to
                         calculate the sum of all elements in a tuple,
sum()
                                                                                       Example:
                        provided that the elements are numeric (integers
                         or floats).
                                                                                              numbers = (10, 20, 5, 30)
print(sum(numbers))
                                                                                               #Output: 65
                                                                                       Example:
                                                                                              numbers = (10, 20, 5, 30)
print(min(numbers))
#Output: 5
print(max(numbers))
                                                                                               #Output: 30
                        Find the smallest (min()) or largest (max())
min() and max()
                         element in a tuple.
                                                                                       Syntax:
                                                                                              len(tuple)
                         Get the number of elements in the tuple using
len()
                                                                                       Example:
                         len().
                                                                                              fruits = ("apple", "banana", "orange")
print(len(fruits)) #Returns length of the tuple.
                                                                                               #Output: 3
```
